# Assignment 1

Discuss:

Battery size and max\_steps

Robustness (Obstacles)

Noisy sensors

# Module Review

Problem Definition, State  
Space, and Uninformed Search

# Definition of a Search Problem

- **Initial state:** state description
- **Actions:** set of possible actions  $A$
- **Transition model:** a function that defines the new state resulting from performing an action in the current state
- **Goal state:** state description
- **Path cost:** the sum of *step costs*

**Important:** The **state space** is typically too large to be enumerated, or it is continuous. Therefore, the problem is defined by initial state, actions and the transition model and not the set of all possible states.

# Complete Planning Agent to Solve a Maze

- The event loop calls the agent function for the next action.
- The agent function follows the plan or calls the planning function if there is no plan yet or it thinks the current plan does not work based on the percepts (replanning).

# Solving Search Problems

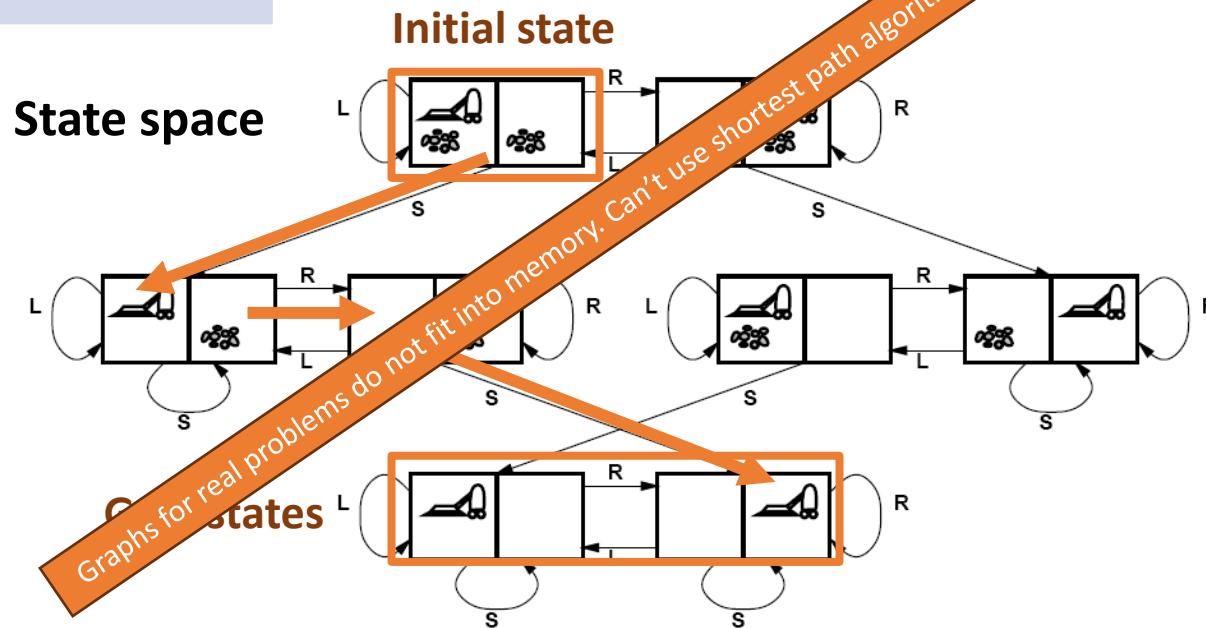

Given a search  
problem definition

- Initial state
- Actions
- Transition model
- Goal state
- Path cost

How do we find the optimal solution (sequence of actions/states)?

Construct a search tree for the state space graph!

# Creating a Search Tree

- Superimpose a “what if” tree of possible actions and outcomes (states) on the state space graph.
- The **Root node** represents the initial state.
- An action child node is reached by an **edge** representing an action. The corresponding state is defined by the transition model.

- Trees cannot have **cycles (loops)**. Cycles in the search space must be broken to prevent infinite loops.
- Trees cannot have **multiple paths to the same state**. These are called redundant paths. Removing other redundant paths improves search efficiency.

- A **path** through the tree corresponds to a sequence of actions (states).
- A **solution** is a path ending in a node representing a goal state.
- **Nodes vs. states**: Each tree node represents a state of the system. If redundant path cannot be prevented then state can be represented by multiple nodes in the tree.

# Differences Between Typical Tree Search and AI Search

## Typical tree search

- Assumes a given tree that fits in memory.
- Trees have by construction no cycles or redundant paths.

## AI tree/graph search

- The search tree is too large to fit into **memory**.
  - a. **Builds parts of the tree** from the initial state using the transition function representing the graph.
  - b. **Memory management** is very important.
- The search space is typically a very large and complicated graph. Memory-efficient **cycle checking** is very important to avoid infinite loops or minimize searching parts of the search space multiple times.
- Checking redundant paths often requires too much memory and we accept searching the same part multiple times.

# State Space

Defines the problem size. Determines:

- Memory requirement: How big will the search tree get?
- Run time: How long will the search take?

# State Space vs. Search Tree Size

- Space and time complexity depend on the **number of tree nodes** searched (created and visited) till a goal node is found. For a tree with  $n$  nodes we have:

$$O(n)$$

- **Remember:** For perfect cycle checking and redundant path elimination, we have a 1:1 mapping between nodes and states:

Nodes in the search tree = states in the search space

Otherwise, we may have multiple nodes representing a state.

- We have the following options to estimate  $n$  for a search problem:
  - a. **Estimate the reachable state space size.**
  - b. **Estimate the number of searched tree nodes.**
- Estimating the complexity is important to judge:
  - How difficult is the problem?
  - What algorithm will fit in memory?
  - Can we find a solution fast enough?
  - Can we find the optimal solution, or do we need to use a heuristic?

# State Space Size Estimation

## State Space

- Number of different states the agent and environment can be in.
- **Reachable states** are defined by the initial state and the transition model. Only reachable states are important for search.

## Estimation

- Even if the used algorithm represents the state space using atomic states, we may know the internal (factored) representation. It can be used to estimate the problem size.
- The basic rule is to estimate the state space size for factored state representation with  $l$  fluents (variables) as:

$$n = |X_1| \times |X_2| \times \cdots \times |X_l|$$

where  $|\cdot|$  is the number of possible values.

## State representation

The factored state consists of variables called fluents that represent conditions that can change over time.

# Examples: What is the State Space Size?

Often a rough upper limit is sufficient to determine how hard the search problem is.

Maze

8-queens problem

8-puzzle problem

Tic-tac-toe

# Examples: What is the State Space Size?

Often a rough upper limit is sufficient to determine how hard the search problem is.

Maze

Positions the agent can be in.

$n$  = Number of white squares.

8-queens problem

All arrangements with 8 queens on the board.

$$n < 2^{64} \approx 1.8 \times 10^{19}$$

We can only have 8 queens:

$$n = \binom{64}{8} \approx 4.4 \times 10^9$$

8-puzzle problem

All arrangements of 9 elements.

$$n \leq 9!$$

Half is unreachable:

$$n = \frac{9!}{2} = 181,440$$

Tic-tac-toe

All possible boards.

$$n < 3^9 = 19,683$$

Many boards are not legal (e.g., all x's)

The actual number can be obtained by a depth-first traversal of the game tree.

# Example: What determines the Search Tree Size?

- $b$ : maximum branching factor  
= number of available actions?

3

- $m$ : the number of actions in any path? Without loops!

4

- $d$ : depth of the optimal solution?

3

## State Space with Transition Model

# Examples: What determines the Search Tree Size?

$b$ : maximum branching factor  
 $m$ : max. depth of tree  
 $d$ : depth of the optimal solution

Often a rough upper limit is sufficient to determine how hard the search problem is.

Maze

8-queens problem

8-puzzle problem

Tic-tac-toe

$b =$

$m =$

$d =$

# Examples: What determines the Search Tree Size?

$b$ : maximum branching factor  
 $m$ : max. depth of tree  
 $d$ : depth of the optimal solution

Often a rough upper limit is sufficient to determine how hard the search problem is.

Maze

$b = 4$  actions  
 $m =$  longest path to the goal or a dead end (bounded by  $x \times y$ )  
 $d =$  shortest path to the goal (bounded by  $x \times y$ )

8-queens problem

$b = ?$  What are the actions? Moving one Queen:  $64 - 7 = 57$   
 $m =$  We may have to try all:  $\binom{64}{8} \approx 4.4 \times 10^9$   
 $d =$  move each queen in the right spot = 8

8-puzzle problem

$b = 4$  actions to move the empty tile.  
 $m =$  Try all  $O(9!)$   
 $d = ???$

Tic-tac-toe

$b = 9$  actions for the first move.  
 $m = 9$   
 $d = 9$  (if both play optimal)

# Uninformed Algorithms

Breadth-first vs. Depth-first Search

# Breadth-First Search (BFS)

All nodes are in memory!

**Expansion rule:** Expand shallowest unexpanded node in the frontier (=FIFO).

**Figure 3.8** Breadth-first search on a simple binary tree. At each stage, the node to be expanded next is indicated by the triangular marker.

## Data Structures

- **Frontier** data structure: holds references to the green nodes (green) and is implemented as a FIFO **queue**.
- **Reached** data structure: holds references to all visited nodes (gray and green) and is used to prevent visiting nodes more than once (cycle and redundant path checking).
- Builds a **complete tree** with links between parent and child.

This is a generalization of Breadth-first search that expands the search based on cost and not on the number of steps.

## Implementation: Best-First Search Strategy

```
function UNIFORM-COST-SEARCH(problem) returns a solution node, or failure  
  return BEST-FIRST-SEARCH(problem, PATH-COST)
```

Path cost with a cost of 1 per action makes the priority queue behave like a FIFO queue!

```
function BEST-FIRST-SEARCH(problem, f) returns a solution node or failure  
  node  $\leftarrow$  NODE(STATE=problem.INITIAL)  
  frontier  $\leftarrow$  a priority queue ordered by f, with node as an element  
  reached  $\leftarrow$  a lookup table, with one entry with key problem.INITIAL and value node  
  while not IS-EMPTY(frontier) do  
    node  $\leftarrow$  POP(frontier)  
    if problem.IS-GOAL(node.STATE) then return node  
    for each child in EXPAND(problem, node) do  
      s  $\leftarrow$  child.STATE  
      if s is not in reached or child.PATH-COST < reached[s].PATH-COST then  
        reached[s]  $\leftarrow$  child  
        add child to frontier  
  return failure
```

The order for expanding the frontier is determined by  $f(n)$  = path cost from the initial state to node  $n$ .

This check is added to BFS! It visits a node again if it can be reached by a better (cheaper) path.

```
function EXPAND(problem, node) yields nodes  
  s  $\leftarrow$  node.STATE  
  for each action in problem.ACTIONS(s) do  
    s'  $\leftarrow$  problem.RESULT(s, action)  
    cost  $\leftarrow$  node.PATH-COST + problem.ACTION-COST(s, action, s')  
    yield NODE(STATE=s', PARENT=node, ACTION=action, PATH-COST=cost)
```

# Depth-First Search (DFS)

- **Expansion rule:** Expand deepest unexpanded node in the frontier (last added).
- **Frontier: stack (LIFO)**
- **No reached data structure!**

**Cycle checking** checks only the current path.

**Redundant paths** can not be identified and lead to replicated work.

**Figure 3.11** A dozen steps (left to right, top to bottom) in the memory-efficient depth-first search on a binary tree from start state A to goal M. The frontier is the set of nodes that have been expanded but whose children have not yet been generated. The node to be expanded next is marked with a red arrow. Previously expanded nodes have faint dashed lines. Expanded nodes with no children (very faint lines) can be discarded.

Memory management:  
only the current path is  
in memory!

# Iterative Deepening Search (IDS)

limit: 0

limit: 1

limit: 2

limit: 3

This is a very important algorithm in AI!

# Implementation: DFS (called iteratively by IDS)

- DFS could be implemented like BFS/Best-first search, just taking the last element from the frontier (LIFO). However, to reduce the space complexity to  $O(bm)$ , **no reached data structure can be used!**
- Options:
  - **Iterative implementation:** Build the tree, and abandoned branches are removed from memory. Cycle checking is only done against the current path. This is similar to Backtracking search.
  - Recursive implementation: Cycle checking is an issue because the current path is stored in the function call stack, which is not accessible to the function. An additional data structure that contains the nodes in the current path can be used.

DFS uses  $\ell = \infty$

```
function DEPTH-LIMITED-SEARCH(problem,  $\ell$ ) returns a node or failure or cutoff
  frontier  $\leftarrow$  a LIFO queue (stack) with NODE(problem.INITIAL) as an element
  result  $\leftarrow$  failure
  while not IS-EMPTY(frontier) do
    node  $\leftarrow$  POP(frontier)
    if problem.IS-GOAL(node.STATE) then return node
    if DEPTH(node) >  $\ell$  then
      result  $\leftarrow$  cutoff
    else if not IS-CYCLE(node) do
      for each child in EXPAND(problem, node) do
        add child to frontier
  return result
```

Memory management: remove nodes for abandoned branches here!

**Cycles:** Prevent cycles by checking against the current path. We also need to ensure that the frontier does not contain the same state more than once.

**Redundant paths:** We cannot prevent other redundant paths.

See BFS for function EXPAND.

# Summary: All Search Strategies

b: maximum branching factor of the search tree  
 d: depth of the optimal solution  
 m: maximum length of any path in the state space  
 C\*: cost of optimal solution

	Algorithm	Complete?	Optimal?	Time complexity	Space complexity
Uninformed Search	BFS (Breadth-first search)	Yes	If all step costs are equal	$O(b^d)$	$O(b^d)$
	Uniform-cost Search	Yes	Yes	Number of nodes with $g(n) \leq C^*$	
	DFS	In finite spaces (cycles checking)	No	$O(b^m)$	$O(bm)$
	IDS	Yes	If all step costs are equal	$O(b^d)$	$O(bd)$
Informed Search	Greedy best-first Search	In finite spaces (cycles checking)	No	Depends on heuristic Best case: $O(bd)$ Worst case: $O(b^m)$	
	A* Search	Yes	Yes	With a good heuristic Number of nodes with $g(n) + h(n) \leq C^*$	

# Module Review

Informed Search

# Assignment 2

Introduction

# Summary: All Search Strategies

b: maximum branching factor of the search tree  
 d: depth of the optimal solution  
 m: maximum length of any path in the state space  
 C\*: cost of optimal solution

	Algorithm	Complete?	Optimal?	Time complexity	Space complexity
Uninformed Search	BFS (Breadth-first search)	Yes	If all step costs are equal	$O(b^d)$	$O(b^d)$
	Uniform-cost Search	Yes	Yes	Number of nodes with $g(n) \leq C^*$	
	DFS	In finite spaces (cycles checking)	No	$O(b^m)$	$O(bm)$
	IDS	Yes	If all step costs are equal	$O(b^d)$	$O(bd)$
Informed Search	Greedy best-first Search	In finite spaces (cycles checking)	No	Depends on heuristic Best case: $O(bd)$ Worst case: $O(b^m)$	
	A* Search	Yes	Yes	Number of nodes with $g(n) + h(n) \leq C^*$ With a good heuristic	

# Properties of Heuristic Functions

- Evaluates a given node  $n$ .
- Provide a **good approximation** of the actual cost from node  $n$  to the goal state.
- Can be computed using additional **information that is known** to the agent or can be obtained via percepts.
- Are **fast to compute** (compared to solving the problem).
- For A\* Search: be **admissible** (never overestimate the cost)
- Search algorithms will expand nodes with better heuristic values/estimated total cost first.

# Implementation

Greedy Best-First search

Best-First  
Search

+

Expand the frontier  
using  
 $f(n) = h(n)$

A\* Search

Best-First  
Search

+

Expand the frontier  
using  
 $f(n) = h(n) + g(n)$

# Heuristics from Relaxed Problems

**What relaxations are used in these two cases?**

**Euclidean distance**

Start state

Goal state

**Manhattan distance**

Start state

Goal state

**Which heuristic is admissible for A\* search?**

# Satisficing Search: Weighted A\* Search

- Often it is sufficient to find a **“good enough” solution** if it can be found very quickly or with way less computational resources. I.e., **expanding fewer nodes**.
- We could use inadmissible heuristics in A\* search (e.g., by multiplying  $h(n)$  with a factor  $W$ ) that sometimes overestimate the optimal cost to the goal slightly.
  1. It potentially reduces the number of expanded nodes significantly.
  2. **This will break the algorithm’s optimality guaranty!**

$$f(n) = g(n) + W \times h(n)$$

Weighted A* search:	$g(n) + W \times h(n)$	$(1 < W < \infty)$
---------------------	------------------------	--------------------

The presented algorithms are special cases:

A* search:	$g(n) + h(n)$	$(W = 1)$
Uniform cost search/BFS:	$g(n)$	$(W = 0)$
Greedy best-first search:	$h(n)$	$(W = \infty)$

# Case Study: A Heuristic for Tic-Tac-Toe

- Define the goal states:
- What is the cost that needs to be estimated?
- What could be used as a heuristic value for these boards (assume you play x):
- How do you calculate the heuristic value?
- Is the heuristic admissible?
- Does the heuristic use a relaxation?
